

SSBP1 faux pas in mitonuclear tango causes optic neuropathy

Lina Zelinger, Anand Swaroop

J Clin Invest. 2020;130(1):62-64. <https://doi.org/10.1172/JCI132532>.

Commentary

Mitochondrial dysfunction or loss is evident in neurodegenerative diseases. Furthermore, mitochondrial DNA (mtDNA) mutations associated with NADH dehydrogenase subunits and nuclear gene mutations that affect mitochondrial function result in optic neuropathies. In this issue of the *JCI*, Del Dotto et al. and Piro-Mégy et al. identify heterozygous mutations in nuclear-encoded mitochondrial single-strand binding protein 1 (SSBP1) in patients with apparently dominant optic neuropathy with or without extraocular phenotypes. Both research groups reported similar mitochondrial findings in response to *SSBP1* mutations. However, the specific SSBP1 mitochondria-associated function in retinal ganglion cells (RGCs) and the resulting optic nerve remains unclear. We suggest that high expression of SSBP1 during RGC differentiation is critical for mtDNA maintenance to produce appropriate optic nerve connectivity and that *SSBP1* mutations in dominant optic atrophy patients do not permit stable binding to N6-methyldeoxyadenosine on the heavy strand involved with replication, leading to disruptions of mtDNA and, eventually, optic nerve dysfunction.

SSBP1 faux pas in mitonuclear tango causes optic neuropathy

Lina Zelinger and Anand Swaroop

Neurobiology-Neurodegeneration and Repair Laboratory, National Eye Institute, NIH, Bethesda, Maryland, USA.

Mitochondrial dysfunction or loss is evident in neurodegenerative diseases. Furthermore, mitochondrial DNA (mtDNA) mutations associated with NADH dehydrogenase subunits and nuclear gene mutations that affect mitochondrial function result in optic neuropathies. In this issue of the JCI, Del Dotto et al. and Piro-Mégy et al. identify heterozygous mutations in nuclear-encoded mitochondrial single-strand binding protein 1 (SSBP1) in patients with apparently dominant optic neuropathy with or without extraocular phenotypes. Both research groups reported similar mitochondrial findings in response to SSBP1 mutations. However, the specific SSBP1 mitochondria-associated function in retinal ganglion cells (RGCs) and the resulting optic nerve remains unclear. We suggest that high expression of SSBP1 during RGC differentiation is critical for mtDNA maintenance to produce appropriate optic nerve connectivity and that SSBP1 mutations in dominant optic atrophy patients do not permit stable binding to N6-methyldeoxyadenosine on the heavy strand involved with replication, leading to disruptions of mtDNA and, eventually, optic nerve dysfunction.

Mitochondrial dysfunction in optic neuropathies

Optic neuropathies are a heterogeneous group of inherited diseases affecting the optic nerve. Axons of retinal ganglion cells (RGCs) form the optic nerve, which transmits visual information from the retina to the visual cortex. Defects in RGC function are associated with vision impairment in glaucoma, Leber optic atrophy (OMIM 535000), and other neuropathies. Leber hereditary optic neuropathy (LHON) was the first reported mitochondrial DNA (mtDNA) disease (1), with male patients being two to five times more likely to develop blindness than females. Color vision is severely affected in LHON from early stages, and visual acuity can deteriorate to 20/200 (legal blindness) or only light perception. Some LHON patients show extraocular phenotypes, such as car-

diac conduction abnormalities, dystonia, and multiple sclerosis-like illness. Autosomal dominant optic atrophies (DOAs) are caused by mutations in nuclear-encoded *OPA* genes that affect diverse mitochondrial functions. DOAs present a much earlier age of onset than LHON, yet most patients report only mild to medium reduction in visual acuity, dyschromatopsia, and/or abnormalities in visual evoked potentials. Additional clinical phenotypes in DOA may include hearing loss, peripheral neuropathy, myopathy, ataxia, and chronic progressive external ophthalmoplegia.

Maintenance of healthy mitochondria requires recurring fission and fusion for repairing damaged components and is especially critical in neurons with extensive axonal/dendritic processes because of high local demands for energy and of metabolites (2). Nuclear genes provide almost

all of the necessary mitochondrial proteins, whereas the mitochondrial genome encodes only 37 genes that are critical for survival. LHON is exclusively caused by mutations in the mitochondrial genes encoding NADH dehydrogenase subunits of complex I; therefore, it exhibits a maternal inheritance pattern. LHON mutations exhibit low penetrance and varying prognosis, indicating the need for additional factors to produce clinical manifestations. The most well-studied nuclear *OPA* gene encodes intramitochondrial Dynamin GTPase *OPA1* (OMIM 165500), which participates in maintenance of mitochondrial genome integrity, replication and distribution of mtDNA, mitochondrial fusion, and energy metabolism (3). Mitonuclear crosstalk is essential for numerous cellular processes, yet how changes in mtDNA and nuclear *OPA* mutations largely affect RGCs and the optic nerve is unclear.

Nuclear protein influencing mtDNA replication/repair

In this issue of the *JCI*, two reports, Del Dotto et al. and Piro-Mégy et al. (4, 5), add further mystery to the continuing saga of the mitonuclear tango. Both groups identified a total of six different mutations in a nuclear gene encoding mitochondrial single-strand binding protein (SSBP1) in multiple families with autosomal dominant optic neuropathy (with and without extraocular phenotypes). The two research groups revealed different genetic trajectories, yet both reached the same conclusion and presented similar biochemical findings (using patient fibroblasts). Key points include a marked depletion of mtDNA with impaired replication rate, defective mitochondrial structure and respiration, modeling of SSBP1 predicting the effect of the mutations, and the absence of SSBP1 tetramers (4, 5). Del Dotto and colleagues were also able to reproduce some of the disease-associated phenotypes in a zebrafish *ssbp1*-knockout model generated by CRISPR-Cas9 (4). Another recent report

further validates *SSBP1* as the bona fide cause of DOA (6).

SSBP1 is part of the mtDNA replication, maintenance, and repair machinery, together with the mitochondrial polymerase ($POL\gamma$), mtDNA helicase (TWINKLE), and mtRNA polymerase ($POLRMT$) (7, 8). mtDNA replication is proposed to initiate at the origin of the heavy (H) strand, and DNA synthesis then proceeds to produce a new H-strand (9). *SSBP1* binds as a

tetramer to the displaced parental H-strand to protect it against nucleases, prevent secondary structure formation, and stimulate TWINKLE's helicase activity as well as increase the processivity of $POL\gamma$ (10, 11). Retrograde translocation of mitochondrial *SSBP1* into the nucleus as a response to proteotoxic stresses helps in cell survival and maintenance of mitochondrial membrane potential by augmenting heat shock factor HSF1 (12). Functional relevance of

SSB proteins has been suggested in DNA damage response (13).

Mitochondrial dysfunction as well as single-strand breaks have commonly and independently been associated with neurodegeneration (14–16). High penetrance of optic neuropathies in patients with *SSBP1* mutations raises a number of questions, the primary one being, why are only RGCs and the optic nerve, and not other neurons, affected? Is mitochondrial maintenance

and damage response machinery different in RGCs? Are specific subtypes of RGCs more affected? Why is there no involvement of other CNS neurons even though dysregulation of mitochondrial biogenesis and mitochondrial DNA depletion have been observed in Parkinson's neurons (17, 18)?

A model suggesting how *SSBP1* mutations affect mitochondrial function

The mammalian retina has five major types of neurons, and RGCs are among the first cells born during development (Figure 1A). High expression of *SSBP1* is evident at E12 at the time of RGC birth in both bulk and single-cell RNA-Seq data, with lower transcript levels observed in mature retina (Figure 1B and refs. 19, 20). We therefore hypothesize that *SSBP1* is needed for mitochondrial biogenesis during early RGC differentiation. Notably, mitochondria enter RGC dendrites before branching patterns are established, and the dendritic mitochondria gradually become enriched (>15-fold) near branch points (21). Thus, RGCs appear to require mitochondria in order to maintain the synaptic landscape. Without healthy mitochondria, the ability of RGCs to transmit visual information might be compromised, likely leading to the scotomas that patients report. Disruption of mitochondrial fusion in *OPA1*^{-/-} mice is reported to result in shortened mitochondria, which accumulate in proximal RGC dendrites; and the number of excitatory synapses and branches of RGC dendrites decline with age (22), further highlighting the importance of mitochondrial fusion for dendritic and synaptic integrity.

To explain how *SSBP1* mutations affect mitochondrial function, especially in developing RGCs, we propose a model shown in Figure 1C, as follows. Genome-wide mapping studies have uncovered asymmetric enrichment of N6-methyldeoxyadenosine (6mA) clusters on the H-strand of mtDNA, and 6mA could destabilize double-stranded DNA, promoting the recruitment of *SSBP1* (23). Increased accumulation of 6mA disrupts oxidative phosphorylation (23) and might lead to impaired response to stress and probably neuropsychiatric disorders (24). We hypothesize that the harsh environment

in the mitochondria results in enhanced accumulation of 6mA on the H-strand of mtDNA and that mutant *SSBP1* protein is unable to form stable tetramers, leaving it vulnerable to damage. Increased accumulation of 6mA, combined with mutant *SSBP1*, could result in errors (including depletion) during mtDNA replication and/or repair, eventually leading to mitochondrial dysfunction or loss. Future studies directed at protecting single-stranded DNA for error-free mtDNA repair or replacement of the damaged H-strand DNA would help in maintaining healthy mitochondria and designing a treatment of optic atrophies.
